# New Mexico's Forest Resources 

Dwane D. Van Hooser

Renee A. O'Brien
Dennis C. Collins

## THE AUTHORS

DWANE D. VAN HOOSER is program manager of the Forest Survey Program at the Intermountain Research Station, Ogden, UT. He holds a B.S. degree in forestry and an M.S. degree in forestry and business management from Southern Illinois University, Carbondale. He began his Forest Service career in 1964 with the Southern Forest Experiment Station, New Orleans. Before coming to Ogden, he held a staff position at the Forest Service national headquarters in Washington, DC.
RENEE A. O'BRIEN is a range scientist and team leader for research in the Forest Survey Program, Intermountain Research Station. She holds a B.S. degree in botany from Weber State University, Ogden, UT, and B.S. and M.S. degrees in range science from Utah State University, Logan. She began her professional career with the Forest Service in 1981 with the Intermountain Station.

DENNIS C. COLLINS is a forester in the Forest Survey Program at the Intermountain Research Station. His primary area of responsibility is resource analysis. He holds a B.S. degree in forest management from the University of Montana. He began his Forest Service career in 1978 with the Intermountain Station.

## RESEARCH SUMMARY

The forest land base in New Mexico totals more than 15 million acres, of which 1.5 million acres are in a reserved status that precludes certain activities, such as wood cutting. Of the more than 13 million nonreserved acres, more than 56 percent are administered by public agencies. Stands of timber species are found on 6.1 million acres. The woodland resource, typified by stands of pinyon-juniper, accounts for more than 9.0 million acres. These areas contain wood volumes of 6.0 billion cubic feet and 5.8 billion cubic feet, respectively. This report presents additional information on the land base, timberland and woodland area, and associated inventory volume, growth, mortality, and removals.

## PREFACE

The primary objective of Forest Survey-a continuing, nationwide undertaking of the Forest Service, U.S. Department of Agriculture-is to assess the renewable resources on the Nation's forest lands. Periodic State-by-State resource inventories are key to accomplishing the objective. Forest Survey was initially authorized by the McSweeney-McNary Act of 1928.

Its current mandate is the Renewable Resources Research Act of 1978.
The Intermountain Research Station with headquarters in Ogden, UT, conducts the forest resource inventories for the Rocky Mountain States of Arizona, Colorado, Idaho, Montana, New Mexico, Nevada, Utah, and Wyoming. These inventories provide information on the extent and condition of the forests-their wood volume and wood growth removals, and mortality for State, privately owned, and most other forest lands outside the National Forest System. These data, when combined with similar information on Na tional Forest lands, provide a basis for forest policies and programs for the orderly development and use of renewable resources.

## ACKNOWLEDGMENTS

The Intermountain Research Station gratefully acknowledges the cooperation of the State Office of the Bureau of Land Management and of the Bureau of Indian Affairs, both in the U.S. Department of the Interior. We extend a special note of gratitude to Bill Chapel and James Norwick, former New Mexico State Foresters; to Ray Gallegos, New Mexico State Forester and his staff; and to the private land owners who provided information and access to field sample locations.
The cover illustration was drawn by Myrna Finke, visual information specialist in the Bureau of Land Management's Albuquerque District Office.

## HIGHLIGHTS

## Area

- Total land area in New Mexico is 77.7 million acres.
- Forests cover about 15.2 million acres; 6.2 million are timberland, and 9 million are woodland.
- Sixty percent of the forest is in the public domain, with most in the National Forest System.
- Some 23 percent of the timberland area is reserved from timber harvesting, but 4.8 million acres are not.
- About 81 percent of the nonreserved timberland is in sawtimber-size stands.
- Ponderosa pine is the dominant forest cover type, occupying nearly 3 million acres, or roughly 60 percent of the timberland.
- Of the 8.9 million acres of nonreserved woodland forest, 4.8 million are in the public domain.
- Over 85 percent of the woodland forests are pinyonjuniper.

## Volume

- Net volume of growing stock on nonreserved timberland is 6 billion cubic feet; two-thirds is on the Na tional Forests.
- Sawtimber volume is about 19 billion board feet (Scribner).
- The ponderosa pine type contains 43 percent of the volume; most of the remainder is in the Douglas-fir type.
- Most of the volume-87 percent-is in sawtimber stands.
- Seventy percent of the cubic-foot volume is in trees less than 17.0 inches d.b.h.
- Net volume of woodland species on woodland is 5.3 billion cubic feet, with pinyon representing more than half the volume.
- Nearly half of the woodland volume is in the 8.0 - to 14.0 -inch d.r.c. classes.

## Growth

- Net annual growth of growing-stock is about 150 million cubic feet, or 3 percent of the volume; 136 million of the annual growth is in softwoods.
- Nearly half of the growth is accounted for by ponderosa pine; most of the remainder is in Douglas-fir, white fir, and Engelmann spruce.
- Woodland growth equals 61 million cubic feet. More than half is accounted for by pinyon.

## Mortality

- Growing stock trees containing 14 million cubic feet of volume died in 1986.
- Douglas-fir and ponderosa pine sustained the heaviest losses.
- Small sawtimber trees accounted for 45 percent of softwood mortality, with poletimber-size trees accounting for roughly 25 percent.
- Insects, disease, and weather were the major known causes of morality.
- Practically all of the 2.7 million cubic feet of woodland mortality was in pinyon.

## Removals

- Thirty-one million cubic feet of timber were removed from New Mexico's forests in 1986.
- Pondercsa pine accounted for more than two-thirds of the removals.
- Nearly all of the removals were in the form of
sawlogs.
- More than four-fifths of the total removals came off National Forest System lands.

# New Mexico's Forest Resources 

Dwane D. Van Hooser<br>Renee A. O'Brien<br>Dennis C. Collins

## INTRODUCTION

This resource bulletin presents the major findings of the latest Forest Survey of New Mexico. It combines data collected by the Intermountain Research Station and its cooperators during 1986 and 1987 with information for the National Forests provided by the Forest Service, Southwestern Region.
The data in this report reflect changes from previous reports (Choate 1966). These changes have three basic sources: changes in sampling design and intensity, changes in land classification and use, and biological and physical changes in the forest. The changes in definitions and survey standards make detailed comparisons with previous inventory results unwise. Relative trends in growth, mortality, and harvest levels can be identified. Both the biological and physical changes, as well as land use, are important for the future of the State's forest resources. Figures are in the text near where they are first referenced. Tables are in a separate section. A glossary explains the meaning of specialized terms used in the text, such as poletimber, sawtimber, sawlog portion of sawtimber trees, and rough trees.

## A HISTORICAL BACKDROP

The history of the development of New Mexico's forests follows the general pattern of the Nation. Nomadic tribes of hunter-gatherers known to have inhabited the Southwest as long as 15,000 years ago first used the forests. Over the centuries, the hunting culture gave way to a more communal culture, with settlements sustained by farming. During this period, the great pueblos developed arts, crafts, and religion. Early tribes had hunted and gathered herbs, seeds, and nuts, and some firewood. The later farming cultures continued those uses. Since they did not have strong cutting tools, they fashioned dwellings and other structures from stone and adobe bricks, using small poles for structural support in ceilings and elsewhere. In addition, the forested mountains became sacred grounds for the tribes. The ruins of cities, canals, and other structures remain as evidence of these native Americans.
Next came the Spanish conquistadors and missionaries. Coronado and his legions were looking for gold and exploring the new land; missionaries, such as Father Escalante, were venturing into land now known as New Mexico. They used the forests to provide shelter and food. The Spanish occupation resulted in only modest increases in the use of wood. Architecture and construction showed Spanish influence, but was similar to that of the Indians. Pinyon and juniper were the main species used for firewood and for fenceposts in ranching operations. The forces of nature remained the major physical influence on the forests.

The full economic potential of the Southwest's resources could be captured only after vast improvements in transportation and technology, such as the railroad. The Federal Government gave railroads vast land grants as incentives to offset high risks associated with such ventures. Construction of railroads and towns and development of mines required large quantities of timber. The existence of distant as well as local markets spurred solutions to the problems of accessing timber. Lumbering became an economic enterprise in its own right.
By the end of the 19th Century, unacceptable environmental and social consequences were becoming apparent throughout the West from the essentially free use and grants of public forest land in the name of local economic development. In 1892 the first forest reserve in New Mexico was set aside under provisions of the General Land Law Revisions Act of 1891 in what is now the Santa Fe National Forest. This Act, the legislation granting New Mexico statehood, and other acts that followed created the ownership distribution that exists in New Mexico (fig. 1).
Today, the forests are expected to provide a variety of goods and services. Timber production is a primary use, but so are watershed protection, wildlife habitat, grazing, developed recreation, and wilderness.

## NEW MEXICO'S FOREST LAND

The forests in New Mexico, like those in other Rocky Mountain States, occur in or near mountain ranges (fig. 2). Forests are found in the Sangre de Cristo and San Pedro Mountains in northern New Mexico; in the Zuni, Tularosa, and San Mateo Mountains in western New Mexico; and in the Jicarilla, Capitan, Sacramento, and Guadalupe Mountains in south-central New Mexico. Southwestern New Mexico has a small concentration of forest land at the southern tip of the Peloncillo Mountains. The cottonwood type is one exception to the forest/mountain correlation. Here, the correlation is nearly reversed with cottonwood occurring principally on wet sites in or along major waterways. The Rio Grande River bottom is a good example of prime cottonwood sites.

Generally, the forest land is concentrated in north-central and westcentral New Mexico. If a line were extended from Clayton to Silver City, nearly 90 percent of the State's forest land would be north and west of the line.

New Mexico's varied topography provides landscapes ranging from desert to alpine tundra. The key factors in the forests' location and species composition are climatic available moisture and temperature. Both are strongly influenced by elevation and topography, varying greatly throughout the State. Elevations range from less than 3,000 feet along the Pecos River in the southeast to 13,161 feet atop Wheeler Peak north of Taos.

As in most mountainous areas, species occur in altitudinal zones. At lower elevations, more trees are found on cool, moist north and east slopes, than on south and west slopes that tend to be drier and hotter.

Precipitation in New Mexico is poorly distributed for tree growth. Summer rains usually come during short, high intensity storms. Much of the moisture is lost as surface runoff. Because the humidity is very low, the evaporation rate is high. In addition, the growing season often includes long periods of drought. The air is usually cool at higher elevations, but the sun heats the soil surface, damaging young trees. The mountains experience severe winters with heavy snowfalls and cold temperatures. The
wide variation in moisture and temperature account for the relatively small number of timber species found in the State.

More than 15 million acres of land meet the criteria for forest; that is, at least 10 percent of the area is stocked with forest trees. Forest represents nearly 20 percent of the State's total land area (table 1).

Forest areas are classified into three categories-two determined vegetatively, one determined politically (fig. 3). The political category is "reserved," indicating that an administrative action or statute precludes harvesting. An example would be the Gila Wilderness in west-central New Mexico. Some 1.5 million acres-10 percent of New Mexico's forest area-are reserved.

The two vegetatively determined classifications are based on the composition of the forest area. If the area is at least 10 percent stocked with tree species traditionally used in manufacturing forest products, the area is classified as timberland. Otherwise, the classification is woodland. Timber species are aspen (Populus tremuloides) and cottonwood (Populus spp.) and all conifers except the pinyons and junipers. Woodland species include the pinyons, junipers, and all other tree species not classified as timber species.

## TIMBERLAND

New Mexico has 6.2 million acres of timberland, with 4.8 million potentially available for multiple use (table 1).

Nearly three-fifths of the timberland is administered by public agencies (fig. 4). The National Forest System, which controls nearly 2.7 million acres, represents the largest single "ownership" in the State. The Bureau of Land Management (BLM), New Mexico State Department of Natural Resources, and various county and municipal governments administer just over 135,000 acres of timberland (table 1).

Figure 3-Distribution of forest land area by land class, New Mexico, 1987.

Figure 4-Distribution of timberland area by owner group, New Mexico, 1987.

Timberland areas in private ownership equal nearly 2.0 million acres. Owners vary from individuals to large corporations, including Indian tribes, farmers, and ranchers.

Private landowners are allowed to do more or less what they wish to their lands. Public agencies, on the other hand, are governed by specific rules, regulations, and processes. The National Forest Management Act, the National Forest Land Policy and Management Act, and the National Environmental Policy Act direct how management plans are to be developed and what they are to contain. Whereas private owners decide how to manage their lands, the entire populace of the United States has a say in how public lands are managed.

One of the most fundamental classifications of timberland is forest type, based on the tree species that represents the dominant component of the stand. Forest type is an indicator of current condition. It usually represents a seral stage, rather than the climax potential of the forest. It is an indicator of the types of consumptive and nonconsumptive products a forest area might produce, providing managers some understanding of management options. In few instances is a stand composed of a single species. Usually, the type indicator will be the species that accounts for the most stocking in the stand, while other associated species are less abundant.

## PONDEROSA PINE

The ponderosa pine type is New Mexico's most extensive timberland type, accounting for about 2.9 million acres, or 60 percent of the State's timberland (table 5; fig. 5). It usually grows between 6,000 and 8,500 feet in elevation. This type is characterized by ponderosa pine (Pinus ponderosa) growing in pure stands (fig. 6), or in association with Douglas-fir (Pseudotsuga menziesii) in the mountains, or Gambel oak (Quercus gambelii) and pinyon (Pinus edulis) in the foothills.

Figure 5-Distribution of timberland area by forest type, New Mexico, 1987.

Figure 6-Ponderosa pine stand in the Gila Wilderness, NM.

Ponderosa pine has always been the mainstay of the timber industry in New Mexico. Large-scale use began after construction of the first railroads. Ponderosa pine forests near Las Vegas, Pecos, and Santa Fe were heavily exploited for ties and construction materials between 1878 and 1881. Later, the wood's versatility brought demand for many other uses, such as poles, posts, mine timbers, and-most of all-lumber. About 73 percent of the lumber cut by New Mexico sawmills has been ponderosa pine. Although other species have gradually become more important, in 1986 ponderosa pine still accounted for 69 percent of the State's total timber products.

## DOUGLAS-FIR

In New Mexico, Douglas-fir grows as a timber type on 842,000 acres, or 18 percent of the timberland area, second only to ponderosa pine. Douglasfir seldom grows in pure stands. Within the species' 8,000 - to 9,500 -foot elevational range, it mixes with ponderosa pine at lower elevations and with true firs (Abies spp.) and spruce (Picea spp.) at higher elevations. White fir (Abies concolor) and aspen are common associates throughout the Douglas-fir type. Eighty-one percent of the area of Douglas-fir type is classed as sawtimber (table 5; fig. 7).

Figure 7-Douglas-fir stand in Jemez Canyon, NM.

Figure 8-Spruce-fir stand on the Cibola National Forest, NM.

The area of the Douglas-fir type is decreasing, but not as rapidly as other types, especially ponderosa pine. Many existing aspen and ponderosa pine stands have an understory of Douglas-fir and white fir that will eventually replace the overstory unless management practices or fire change the successional trend.

Douglas-fir is suitable for many uses. Timber has been sawed into boards, dimension stock, sheathing, flooring, and railroad ties for many years. Before 1962, Douglas-fir was almost always second to ponderosa pine in volume sawed for lumber. In 1962, however, the 47 -million-boardfoot cut of Douglas-fir fell behind ponderosa pine and Engelmann spruce. By 1986, it had again become the second most harvested species.

## SPRUCE-FIR

Spruce-fir stands, mostly found just below timberline, have a mixture of species. Engelmann spruce (Picea engelmannii) is the most important commercial tree, although subalpine fir (Abies lasiocarpa) is generally as numerous in the stand (fig. 8). Other species that occur less frequently include corkbark fir (Abies lasiocarpa var. arizonica), white fir, and Douglas-fir, as well as limber (Pinus flexilis) and bristlecone (Pinus aristata) pines.

About 70 percent of the 228,000 acres of spruce-fir type is in sawtimber stands (table 5). Although the area of the spruce-fir type is relatively small, it is important for water yield. Since these lands receive more precipitation per acre than any other class of forest, water runoff is high. Recreation values are also significant, particularly for wilderness travel.

## WHITE FIR

The white fir forest type covers about 464,000 acres, or 10 percent of New Mexico's timberland. Occurring above 8,000 feet in the south to above 11,000 feet in the north, this type consists of white fir trees growing in association with Douglas-fir, ponderosa pine, and aspen (table 5). In young stands the trees tend to form full crowns and are often harvested for Christmas trees. Mature stands will contain trees in excess of 25 inches diameter at breast height (d.b.h.) and over 100 feet tall (fig. 9).
White fir generally produces poor-quality wood. The trees are highly susceptible to heart rot and windshake. They also tend to shatter easily when felled. The type provides good wildlife habitat, especially seeds for food. Red squirrels cache and eat the seeds. The type is also valuable for watershed protection and esthetics (Healy 1991).

Figure 9-White fir stand at about 9,000 feet elevation, New Mexico.

Figure 10-Mature aspen stand, with ponderosa pine understory, near Los Alamos, NM.

## ASPEN

Aspen is the predominant species on 140,000 acres of timberland in the State. Aspen grows almost entirely in single-aged stands, many of which originated after fires within the last 100 years. An understory of mixed conifers is common (fig. 10).

Although little aspen is being harvested now, it is well suited for pulpwood, excelsior, core stock, and lumber for certain uses. Demand could develop in New Mexico as it has elsewhere.

Aspen stands are also important for other resource values. Aspen root sprouts, and forbs and understory vegetation are excellent forage for big game and livestock. On well-managed lands, aspen is considered as satisfactory as conifers for watershed protection. However, it is a better soil builder. Aspen's brilliant autumn foliage is one of the forest's main scenic attractions.

## Stand Size

Timberland in New Mexico is dominated by stands of sawtimber-size trees. In all, some 3.9 million acres are in this category (fig. 11; table 5).

Figure 11-Distribution of timberland area by stand-size class, New Mexico, 1987.

Poletimber-size trees comprise the dominant component on nearly 700,000 acres, with slightly less than 1 percent of the area in seedling/sapling stands. An additional 159,000 acres are considered timberland, but because of recent harvesting are less than 10 percent stocked. The relative distribution of stand-size classes within each ownership closely follows the distribution for all ownerships. Sawtimber stands dominate, followed by poletimber, and so forth.

Productivity Class

New Mexico's timberland is not among the most productive in the West, but certain individual forest types demonstrate relatively high growth potential. About a third of the area has the ability to produce more than 50 cubic feet per acre per year, including 237,000 acres that could produce more than 85 cubic feet per acre per year in stands that totally occupy the available growing space. The majority of the area is much less productive, capable of growing no more than 50 cubic feet per acre per year (table 5).

The ponderosa pine type usually occurs just above the pinyon-juniper type on drier sites that receive limited moisture. This type accounts for more than 60 percent of the timberland in the State, but only 11 percent has an annual productivity potential of 50 cubic feet or more per acre. The more productive types such as spruce, white fir, and aspen, occur on cooler, more moist sites. They account for just 16 percent of the area, but at least two-thirds of these types have a wood-growing potential exceeding 50 cubic feet per acre per year. Some lands have the potential to produce 120 cubic feet per acre per year or more (table 5).

Major forest type

## Potential for growing <br> 50+ cubic feet/acre/year <br> Percent of type

## Stand Composition

Since a large proportion of the timbered acres support stands of sawtimbersize trees, fairly high board-foot volumes per acre would be expected (fig. 12). On average, New Mexico's timberland contains 4,835 board feet per acre. The 1,500- to 5,000-board-foot class accounts for nearly half of the timberland area. Sixteen percent of the area contains less than 1,500 board feet per acre, while 10 percent supports stands containing more than 10,000 board feet per acre (table 9).

Within each owner group, the 1,500- to 5,000-board foot per acre category is the dominant classification, but the relative position of the other categories differs for different ownerships (fig. 12). On the National Forests, more area is in the higher volume classes. For example, 43 percent of the timberland on National Forests contains more than 5,000 board feet per acre, and 75 percent of the $10,000+$-board-foot-per-acre category is on the National Forests. Nearly 80 percent of the private timberlands supports stands containing less than 5,000 board feet per acre, with only 7 percent having stands containing more than 10,000 board feet per acre (table 9 ).

New Mexico's timberlands contain an estimated 1.7 billion trees, nearly all meeting the minimum merchantability standards for growing stock. Altogether, some 1.6 billion- 96 percent-are in this classification (table 11). Of those trees not classified as growing stock, one-half are salvable dead. The remainder consists of cull trees. Of those, nearly three-fourths are considered rotten culls (table 12).
Most growing-stock trees are conifers, while just 12 percent are hardwoods, cottonwood and aspen. The dominant conifer is ponderosa pine, accounting for 47 percent of the softwood stand table (fig. 13). The next most abundant conifer is Douglas-fir with 292 million stems or 21 percent of the stand table. White fir accounts for 13 percent of the standing inventory,

Figure 12-Distribution of timberland area by stand-volume class, and by stand-volume class and owner group, New Mexico, 1987.

Figure 13-Distribution of growing-stock trees on timberland by species, New Mexico, 1987.
with Engelmann spruce accounting for 9 percent. The remaining 10 percent of the forest is composed of subalpine fir, limber pine, and bristlecone pine (table 11).
Most of New Mexico's timberlands contain significant numbers of sapling-size trees (fig. 14). Fully 55 percent of the softwood inventory and 65 percent of the hardwood stands are in this size class. The proportion of poletimber-size trees is about equal for softwoods and hardwoods, 28 and 31 percent, respectively. Sawtimber-size trees are 17 percent of the softwood stands, while just over 4 percent of the hardwoods are in this size class (table 11).
Generally speaking, stands exhibiting the size class distribution in figure 14 are considered to have a reasonably balanced structure for future development. If this distribution is representative of stands throughout the State, then forest cover will certainly be maintained, if not increased.

The volume of wood found in trees may be measured in cubic feet, the total volume of wood that could potentially be used, or in board feet, the volume that could potentially be used by a sawmill.

## CUBIC VOLUME

New Mexico's timberlands contain 6.2 billion cubic feet of wood volume, with 96 percent in trees meeting growing-stock merchantability standards. Softwood species represent 92 percent, or 5.5 billion cubic feet in trees meeting the merchantability standards. Within the softwood inventory, more than three-fourths of the growing-stock volume is contained within the sawlog portion of sawtimber-size trees. These trees also contain an additional 250 million cubic feet in their upper stem portion. Poletimber-size conifers contain an additional 982 million cubic feet, or 18 percent of the softwood growing-stock inventory (table 22; fig. 15).

Figure 14-Distribution of growing-stock trees on timberland by tree-size class, New Mexico, 1987.

Figure 15-Distribution of cubic-foot volume on timberland by class of timber for softwood and hardwood, New Mexico, 1987.

Of the 172 million cubic feet of softwood volume classified as other than growing stock, nearly three-fourths is salvable dead trees. While the trees have limited utility for the forest products industry, they are preferred by many fuelwood cutters and are valuable for cavity-nesting birds. These trees also are critical for ecosystem functions.
The remaining softwood volume is cull trees, about evenly distributed between rough and rotten trees (table 22). Since cull trees have more than two-thirds of their volume in defective or missing wood, the usable volume represents only one-third of the volume in cull trees. The net volume of 172 million cubic feet of "usable" wood in cull trees could represent a total of nearly a half billion cubic feet. This represents a significant carbon sink. Since increasing levels of atmospheric carbon dioxide could lead to global warming, carbon sinks are gaining attention.
Hardwood species contain 8 percent of the total volume in growing-stock inventory. The majority of the hardwood volume is in poletimber-size trees (fig. 15). Some 280 million cubic feet is contained in this size class. Saw-timber-size trees contain 191 million cubic feet of growing stock, with 94 percent of the volume in the sawlog portion of the bole. Another dissimilarity between the softwood and hardwood inventories is the non-growingstock component. Thirteen percent of the standing hardwood inventory is non-growing stock, compared to 3 percent for softwood. The distribution of this material differs, with hardwoods having slightly less than half in the salvable dead component and less than 10 percent in rough cull trees (table 22).
The dominant species in terms of volume is ponderosa pine. It accounts for nearly 2.5 billion cubic feet of growing stock, equal to 42 percent of the standing inventory (fig. 16). To put this volume in perspective, it's 10 cubic feet for each man, woman, and child in the United States. Douglas-fir is the next most plentiful species with 1.3 billion cubic feet of volume, or 22 percent of the inventory. Two species-white fir and Engelmann sprucetogether account for 22 percent of the inventory. Aspen, the dominant hardwood, accounts for 448 million cubic feet, or 7 percent of the growingstock volume (table 16).
The distribution of volume by owner group differs somewhat from the distribution of area by owner group (fig. 17). For example, the National Forest System contains 65 percent of the growing-stock volume, but only 56 percent of the timberland area. An inverse relationship exists on private land, which has just 32 percent of the growing-stock volume but accounts for 41 percent of the timbered area. The volume share contained on other public land, 2 percent, is about equal to its area, 3 percent (tables 9 and 16).
The distribution of volume by tree-size class differs considerably between softwoods and hardwoods. Poletimber-size conifers contain 18 percent of the softwood volume, while similar size hardwoods contain 59 percent of the total hardwood growing stock (table 19). Part of this difference can be attributed to the d.b.h. thresholds between poletimber and sawtimber for the species groups. For softwoods, the sawtimber threshold is 9.0 inches; for hardwoods, 11.0 inches. The hardwood poletimber volume summaries include trees from 9.0 to 10.9 inches d.b.h., while the softwood summaries include such trees in sawtimber. This difference only reduces the hardwood poletimber volume by some 20 percent and would result in the hardwood poletimber volume still being 37 percent of the total.

Over half of the softwood growing stock is in small sawtimber, with 30 percent classified as large sawtimber; that is, trees greater than

Figure 16-Distribution of growing-stock volume on timberland by species, New Mexico, 1987.

Figure 17-Distribution of timberland area and growing-stock volume on timberland by owner group, New Mexico, 1987.
17.0 inches d.b.h. For hardwoods, 32 percent of the growing-stock volume is in small sawtimber-size trees, with less than 10 percent in large sawtimber-size trees (table 19).

The volume of growing stock within each individual species is similar to that for each species group, except for subalpine fir, which has 31 percent of the volume in poletimber-size trees, 56 percent in small sawtimber-size trees, and only 13 percent in large sawtimber-size trees (table 19).

## SAWTIMBER VOLUME

The growing stock on New Mexico's timberland includes some 23 billion board feet (International $1 / 4$-inch rule) of sawtimber (table 20). The distribution of this material by species follows that for growing stock, with ponderosa pine being dominant. Douglas-fir, with 23 percent of the total sawtimber volume, is second; white fir and Engelmann spruce rank third and fourth with 11 and 10 percent, respectively. As with growing stock, aspen is the fifth most abundant species, contributing some 951 million board feet-4 percent-to the sawtimber inventory (table 20).

The distribution of sawtimber by ownership also follows that for growing stock. Lands administered by the National Forest System contain 15.2 billion board feet of sawtimber, representing about two-thirds of the standing volume. Other public ownerships account for 473 million board feet, or 2 percent of the inventory. Private owners have more than 7 billion board feet, or 32 percent of all sawtimber in New Mexico (table 17).

The distribution of softwood volume by tree-size class is split about 60:40 between small sawtimber and large sawtimber; for hardwood species the split is about 80:20. Subalpine fir is an exception for softwood, with 80 percent in small sawtimber trees and just 20 percent in trees over 17.0 inches d.b.h. (table 19).

A comparison of the board-foot and cubic-foot volumes in the sawlog portion of growing-stock trees indicates that the overall size of the population may be decreasing. The distribution of trees by size class is skewed to poletimber and small sawtimber-size trees. For example, the current board foot:cubic foot ratio is 5.2, compared to 5.4 in 1962 (Choate 1966)-a 5 percent reduction. A comparison of volume distribution reflects this trend. In 1962, the volume in trees $17.0+$ inches d.b.h. approached 60 percent of the inventory, compared to 40 percent in 1987.

## Components of Change

To assess forest dynamics, three factors must be examined: the rate at which the forest is growing, the rate at which it is dying, and the rate at which volume is being removed through harvesting.

## GROWTH

New Mexico's forests are adding nearly 164 million cubic feet of growing stock annually to the standing inventory, including 702 million board feet of sawtimber. This represents an annual "rate of return" of nearly 3.0 percent in the absence of mortality. In 1986, 13.8 million cubic feet of growing stock was taken from the inventory after dying, leaving a net increase of 150 million cubic feet (tables 26 and 32). Of the sawtimber-size trees, just over 48 million board feet was taken from the inventory after dying, leaving a net gain of 654 million board feet (tables 27 and 33).

On average, this represents an increase of 31.3 cubic feet per acre per year, only two-thirds of the increase New Mexico's timberlands potentially
could produce (tables 5 and 26). This apparent deficit can be partially explained by current stocking levels and stand structure.
Stocking is an expression of the extent to which trees use the site. It is determined by comparing the actual number of trees or their basal area with a specified standard determined by the forest type. Stands are considered fully stocked when an increase in the number of trees per acre does not increase average growth. This condition usually occurs when per-acre stocking is 60 to 80 percent. As stocking increases above 80 percent, growth begins to decline due to overstocking in growing-stock trees, space preempted by cull trees, or conditions adversely affecting growth such as brush or rock outcroppings.

In New Mexico, only about one-fifth of the stands are fully stocked (fig. 18). A small proportion (some 4 percent) is considered overstocked with growing-stock trees. Stands with medium stocking occur on nearly onethird of the timber acres (table 10). Within these stands, a very small proportion contain inhibiting brush or other conditions precluding seedling establishment or exerting an undue competitive influence affecting growth of growing-stock.
The final stocking components, poorly stocked and nonstocked, occur on more than one-fourth of New Mexico's timbered acres (table 10). Poorly stocked stands are those in which growing-stock trees occupy less than 40 percent of the potential growing space, while nonstocked stands contain virtually no trees. These stands present the best opportunity for increasing net annual growth through intensified management.

Thus, based on stocking alone, full potential growth would be nearly impossible to attain. Producing two-thirds of the potential growth attainable when only 1 acre in 5 is fully stocked is relatively good performance.

Stand structure also affects current growth. Overall, 55 percent of the trees in New Mexico are less than 5.0 inches d.b.h. They do not contribute to growth, but do take space, competing with those trees that do contribute.

Figure 18-Distribution of timberland area by stocking condition, New
Mexico, 1987.

An additional 2 percent of the stands are comprised of large sawtimber trees that are approaching biological maturity and not producing much annual increment. The remainder of the stands are comprised of diameter classes contributing to stand growth. Twenty-eight percent is in poletimbersize trees, and 15 percent is in small sawtimber-size trees (table 11). These trees that comprise less than half of the stand are achieving twothirds of the growth potential of the timbered acres. One final comment relative to stand structure. Some 1.7 billion trees grow on New Mexico's timberlands with 1.6 billion or 96 percent classified as growing stock. Although, the cull and salvable dead trees occupy growing space and compete with growing stock for water and sunlight, they apparently are not as important in affecting growth as stocking.
National Forest System lands outperform those of the other owners (fig. 19). Seventy-one percent of the potential growth is achieved there, compared to 66 percent for all owners and 58 percent for the private sector (tables 6-8 and 26).

Cottonwood leads net annual growth by species with a rate of 4.0 percent. This is not unexpected, since cottonwood grows on moist sites such as those found along the Rio Grande River. Other good performers are aspen and white fir. Both grow at an annual rate of 2.9 percent. New Mexico's dominant species-ponderosa pine-grows at a respectable rate of 2.5 percent.

## MORTALITY

As trees grow, some die. In 1986, trees that died contained 13.8 million cubic feet of growing stock, including 48.3 million board feet of sawtimber (tables 32 and 33 ). This represents 0.2 percent of the standing inventory and 8.4 percent of gross growth. Destructive agents come in many forms. Several may be active on a single tree. As a result, it is often difficult to determine the exact cause of death. In 1986 , some 4.2 million cubic feet of

Figure 19-Potential vs. current net growth of growing stock on timberland by owner group, New Mexico, 1986.

Figure 20-Distribution of growing stock mortality on timberland by cause of death, New Mexico, 1986.
growing stock- 30 percent of total mortality-was taken from the inventory due to unknown causes (fig. 20; table 38).

The leading causes of death that could be determined were insects, disease, and weather. Insects alone killed trees containing 4.7 million cubic feet of growing stock; root rots and stem diseases took out an additional 2.8 million cubic feet. Weather, usually wind and lightning, killed trees with 1.5 million cubic feet of growing-stock volume (table 38).

One species-Douglas-fir-was hit particularly hard. Nearly 6.5 million cubic feet of growing stock was killed in 1986. This represents 0.5 percent of the standing inventory of the species and 47 percent of total mortality. Insects were the most significant cause, accounting for more than 60 percent of the mortality. Insect-killed Douglas-fir was the single largest component of mortality in 1986, nearly equaling the volume lost to unknown causes for all species, and exceeding the total volume lost to disease (table 38). Informed sources felt the mortality was due to an outbreak of Douglasfir beetle (Rogers 1990).

Insects and disease do more than simply kill trees. Insects, such as shoot and tip moths, and diseases, such as dwarf mistletoe, stunt growth and kill young trees. Defoliating insects also reduce growth and kill susceptible trees. As a result it takes longer to produce trees of merchantable size and the stems may be lower quality, making them less useful and desirable forest products.
Some silvicultural techniques are designed to manipulate stands before insects and disease become established. Harvesting larger, older trees is one method to decrease susceptibility to bark beetle. Other techniques include thinnings, and planting resistant species. Chemical controls have been employed with relative success. Because of environmental concerns, chemical controls may well become a technique of the past.

Tree mortality may have positive effects. Foresters sometimes enhance wildlife habitat by producing snags for those birds that glean for their food and for birds that need old, dead trees for nesting cavities.

## REMOVALS

The final component of change is removals. It is categorized as growingstock volume removed as: (1) roundwood harvest for products such as sawlogs, pulpwood, posts, and poles; (2) logging residues; and (3) timber stand improvement and other silvicultural operations, diversion of forest land to nonforest, and land withdrawals for reserved areas such as parks and designated wilderness. Volume estimates for the third category are best generated from remeasurement surveys. This report's inventory data were developed from an initial visit; thus, removals related to diversion of forest land to nonforest or reserved uses will not be included.

Roundwood Harvest-In 1986, 30.1 million cubic feet of growing stock, including 166.2 million board feet of sawtimber, was harvested from New Mexico's timberlands (McLain 1989a). This represents 0.5 percent of the total inventory and 20 percent of net annual growth. Not unexpectedly, the majority of the harvest- 92 percent-was in sawlogs (fig. 21). The remainder was made up of posts, poles (corral and utility), round pulpwood, house logs, and excelsior bolts.

Ponderosa pine accounted for more than two-thirds of the harvest volume. Douglas-fir followed with 16 percent of the harvest, with true firs accounting for 9 percent. Without exception, the harvest volume of each species represented less than 1 percent of its standing inventory. The range was 0.8 percent for ponderosa pine to 0.2 percent for Engelmann spruce.

The National Forests in New Mexico were the main supplier of roundwood, supplying more than four-fifths of the harvest volume. The BLM

Figure 21—Sawlogs being harvested from New Mexico forest.

Figure 22-Broken portion of merchantable stem to be bucked out and left in the woods.
contributed a little volume, with the remaining 16 percent ( 4.7 million cubic feet) coming from privately owned lands.
Nearly 90 percent of the harvest came from six counties, with the remainder coming from eight other counties (McLain 1989a). The production leader was Rio Arriba County with 42 percent of the harvest. Catron and Otero Counties contributed 18 percent and 10 percent of the harvest volume, respectively; Cibola, Sandoval, and San Juan Counties combined for another 18 percent.

Logging Residue-Not all material cut during a roundwood harvesting operation makes it out of the woods. Trees break during felling, with unusable sections cut out and left (fig. 22); some trees are cut with more than a 1 -foot stump; and top sections left behind may have large end diameters greater than 4.0 inches diameter outside bark. Moreover, harvesting operations may damage nonproduct growing-stock trees. Even though this material does not make it to a primary wood-processing plant, it is part of the volume removed from the inventory. McLain (1989b) found that for every 1,000 cubic feet of growing stock delivered to the mill, 33 cubic feet were left in the woods as logging residue. In addition, 10 cubic feet of residue were created by damaging nonproduct trees. These volumes must be included in removals to accurately assesss the impact of harvesting on standing inventory. Some material was harvested from salvable dead trees and from nongrowing-stock portions of live trees. This must be "added" back to balance the removals. In 1986, 30.1 million cubic feet of product volume, including 548,000 cubic feet of salvable dead and nongrowing stock, was delivered to primary processing plants. An additional 1.3 million cubic
feet remained in the woods as logging residue. Thus, total removals from growing stock were 31.2 million cubic feet, including 184.6 million board feet (International 114 -inch rule) (tables 44 and 45).

One "product" accounted for, but usually insignificant in terms of total removals, is fuelwood. In 1986, McLain (1989c) found that just over 5,000 cords were harvested (fig. 23).
Taken together, the components of change indicate that New Mexico's timberlands are sustaining themselves (fig. 24). The 1987 standing inventory of 6 billion cubic feet of growing stock is the result of 164 million cubic feet of growth or 2.7 percent, offset by losses of 14 million cubic feet or 0.2 percent to mortality and 31.2 million cubic feet ( 0.5 percent) to removals. The growing-stock inventory's net annual gain is more than 150 million cubic feet or 2.3 percent.

Figure 23-Fuelwood stacked and ready to use.

## WOODLAND

New Mexico has just over 9.0 million acres of woodlands. Only 1.5 percent are in reserved status (table 1).

The other forest in New Mexico is the area dominated by pinyon-juniper (P-J), the oaks, and, to a limited degree, mesquite (Prosopis spp.). These types, collectively referred to as woodlands, occupy, more than 8.8 million acres. Nearly 89 percent of the woodlands is in P-J (fig. 25). Areas where junipers occur alone account for nearly 7 percent. Oak stands occupy just over 4 percent. Mesquite attained tree form on about 3,500 acres, primarily in southwestern New Mexico, all on National Forest lands (table 50).
The pinyon-juniper type consists of pinyon, the New Mexico State tree, and one or more of the following juniper species: alligator juniper (Juniperus

Figure 24-Comparison of components of change and net inventory gain of growing stock on timberland in New Mexico, 1986.

Figure 25-Distribution of woodland area by forest type, New Mexico, 1987.
deppeana), Rocky Mountain juniper (J. scopulorum), oneseed juniper ( J. monosperma), or Utah juniper (J. osteosperma). Other tree species that may be found in this type are ponderosa pine, limber pine, and various oaks (Quercus spp.) (fig. 26). In the juniper type, one or more of the juniper species dominate the stand.

These types, occupying dry slopes between 4,500 and 8,000 feet, are bordered by and often mixed with ponderosa pine forests at the higher elevations and desert plant communities at the lower elevations. Pinyon-juniper and juniper forests, commonly growing in open conditions, are highly valued for resources such as pinyon nuts, firewood, posts, livestock forage, and seasonal or year-long wildlife habitat.
The oak type is dominated by Gambel oak. Occurring between 5,000 and 8,000 feet elevation, this hardwood community covers 402,000 acres (5 percent) of the State's forest land (table 50). Oak is commonly used for fenceposts and fuelwood (fig. 27).
The distribution of woodland area by owner is almost the reverse of that for timberland (fig. 28). The National Forest System administers 35 percent of woodland. Other public agencies, principally the State and BLM, administer 20 percent, and private owners control 45 percent (table 50).
Woodlands are classified for site productivity and stand volume. Productivity is a measure of how well woodland on the site is able to sustain itself. It is determined by attributes such as soil depth and texture, rockiness,

Figure 26-A typical stand of pinyon-juniper.

Figure 27-A typical Gambel oak stand.

Figure 28-Distribution of woodland area by owner group, New Mexico, 1987.
steepness of slope, and the presence of regeneration. The volume classification could be considered a surrogate for stocking. Sites with low volume per acre could be considered low to nonstocked; those supporting substantial volume could be considered fully stocked.

Fully 86 percent of New Mexico's 8.9 million acres of woodland is in the high productivity class. Pinyon-juniper has 86 percent of its 7.9 million acres in the high productivity category. Four-fifths of the pure juniper type is in the high classification. Pure juniper occurs on the harsher sites, explaining why it is not as likely to be in the high category. Ninety-five percent of the oak and all the mesquite are in the high category (table 51; fig. 29). Oak, which regenerates by sprouting, tends to have adequate regeneration present. Tree-form, mesquite is usually found along draws and washes that have moisture available at least part of the growing season.

## Volume

In terms of volume per acre, the State's woodlands and the acres in P-J tend to "gather" at the extremes. About one-third falls in the less than 400-cubic-feet-per-acre category, while an additional one-fourth of State and P-J woodland acres is in stands supporting 1,000 cubic feet or more (table 52). The juniper and mesquite types have most of their acres at the lower end of the volume scale. Juniper, for example, has two-thirds of its area in stands containing less than 400 cubic feet per acre. All of the mesquite stands are in this category. Oak has 28 percent of its area in stands containing less than 200 cubic feet per acre and nearly as much in stands supporting more than 1,000 cubic feet per acre. More than 60 percent of the high-volume stands are found in National Forests while over half of the low volume stands are privately owned.

New Mexico's woodland acres contain 2.6 billion trees. The majority (54 percent) are pinyon (table 53). One-third of the stems are juniper,

Figure 29-Distribution of woodland area by productivity class within forest type, New Mexico, 1987.

Figure 30-Distribution of cubic volume of woodland species on woodland, New Mexico, 1987.
primarily oneseed. Oaks account for 12 percent of the stems. Gambel oak is dominant, but the oaks include Emory (Quercus emoryi) and evergreen or live oak (Q. turbinella). Miscellaneous species such as mesquite, walnut (Juglans major), and locust (Robinia neomexicana) account for the remaining 1 percent.
Thirty percent of all trees on woodland are below 3.0 inches diameter at the root collar (d.r.c.), the threshold for "merchantable" woodland trees (table 53). Nearly 90 percent are less than 11.0 inches d.r.c. The size distribution for the major woodland species-pinyon, juniper, and oakapproximates that of the State as a whole, while most miscellaneous species are less than 3.0 inches d.r.c.
The 8.9 million acres of woodland contains 5.8 billion cubic feet of wood (table 54). Nearly all of the volume is in woodland species; however, in areas where woodland and timberland intermingle, timber species are found in limited numbers on woodland sites. Five timber species have 433 million cubic feet of wood, 7.5 percent of the total woodland volume. Ponderosa pine has 401 million cubic feet, followed by Douglas-fir with 22 million cubic feet. Limber pine, white fir, and cottonwood account for the rest.
The net volume of woodland species on woodland equals 5.3 billion cubic feet, more than half in pinyon (table 55). The junipers account for 2.4 billion cubic feet ( 44 percent) of the standing volume, with oaks contributing 239 million cubic feet (fig. 30).
Nearly half of the volume is contained in the 8.0 - to 14.0 -inch d.r.c. classes (fig. 31). Another 12 percent is in the 4.0 -inch and 6.0 -inch d.r.c. classes, with the remaining 40 percent in trees over 15.0 inches d.r.c. (table 55).
Another significant component of woodland volume is contained in dead trees or dead portions of live trees. Dead material adds 1.4 billion cubic feet to the volume contained on woodland (table 58). It equals 24 percent of the live volume. More than half of this volume is contained in juniper

Figure 31-Distribution of cubic volume of woodland species on woodland by d.r.c. class, New Mexico, 1987.
trees, with more than 60 percent in high volume or fully stocked stands. In addition, more than half of the dead material is in stands of pinyon and juniper on the National Forests. The distribution of dead volume by tree-size class parallels that of the live volume component. Most of the dead material is on live trees.

## Components of Change

Altogether, the woodland base of 5.3 billion cubic feet is accruing $50 \mathrm{mil}-$ lion cubic feet yearly. This is less than 1 percent of the total inventory. It reflects the loss of 2.7 million cubic feet of mortality in the absence of harvest.

## Product Potential

Merchantability standards for woodland species are essentially in the mind of the consumer. Thus, all 6.7 billion cubic feet of volume is potentially convertible into a "product" (tables 55 and 58). Woodland trees generally produce four marketable commodities-pinyon nuts, Christmas trees, fenceposts, and fuelwood. Pinyon nut production was beyond the scope of the inventory. Suffice it to say that most of New Mexico's pinyon nuts are consumed by humans, pinyon jays, and other wildlife.

## CHRISTMAS TREES

Each pinyon tree tallied on lands outside National Forests was graded for use as a Christmas tree based on its height and form:

## Christmas tree grade

Premium
Standard
Utility
Total

## Percent of inventory

0.5
2.9
8.8
12.2

Assuming that the percentages apply to pinyon growing in National Forests, New Mexico has significant potential for Christmas tree harvest. Of the 720 million pinyon trees growing on National Forests, 88 million would meet minimum grade criteria, bringing the total potential Christmas trees to 171 million statewide. By grade, the breakdown would be: 7 million premium, 41 million standard, and 123 million utility.

## FENCEPOSTS

Similar standards were developed to classify fencepost potential for juniper trees (fig. 32). Assuming fenceposts occur on National Forest lands as frequently as on other lands, the potential fencepost supply is 171 million pieces, with about 60 million pieces meeting minimum standards for the more valuable cornerposts.

## FUELWOOD

Pinyon fuelwood is popular in New Mexico, as in other Western States. In 1986, some 33,000 cords were harvested for fuelwood (McLain 1989c). More than 26,000 cords were cut on private lands. Public lands provided 6,600 cords, most from National Forests. Pinyon was the most favored single species, accounting for nearly 17 percent of all fuelwood harvested.
Juniper species are also commonly used for fuelwood in New Mexico. In 1986, nearly 74,000 cords were harvested (McLain 1989c). The combined fuelwood harvest from junipers amounted to more than 37 percent of the total. Nearly three-fourths of the juniper fuelwood was removed from privately owned woodlands, National Forests produced just over one-fourth. A relatively small amount of juniper fuelwood was harvested from BLM lands.

Figure 32-Juniper fenceposts ready for market.

## FOREST INDUSTRY

By 1883, northern New Mexico was on the main line of a transcontinental railroad. Numerous lines connected various parts of the State's interior. Construction of the railroads sparked a demand for timbers, ties, and other forest products. The railroads delivered logging and milling machinery to the State, later transporting logs to mills and lumber to local and Plains States markets.

Logging, timber treating, and sawmilling began to expand in about 1880 in the Zuni Mountains, extending to north-central New Mexico and to the mountains east of Alamogordo. The State's lumber industry grew at the end of World War I, declined during the brief depression of 1920-21, expanded in 1929, then went into a tailspin during the Great Depression. The industry found firm footing during World War II. Production decreased after the war, then increased sharply after 1949. Timber production peaked at 51 million cubic feet in 1966, declining until 1986 when production equaled 30 million cubic feet.
The timber products industry in New Mexico has always been modest when viewed on a national scale (Baker and others 1988). The same can be said for all the Rocky Mountain States. New Mexico's 1986 production of 30 million cubic feet is far less than 1986 roundwood harvests for six other States, based on the 1990 RPA data base:

| State | Million <br> cubic feet |
| :--- | :---: |
| Maine | 440 |
| North Carolina | 722 |
| Georgia | 1,194 |
| Alabama | 943 |
| Arkansas | 579 |
| Oregon | 1,591 |

At the local level, lumbering is a substantial business in New Mexico. In 1963, 2,200 people, or one of every seven manufacturing workers, were logging, milling, or otherwise converting trees or logs into products (Choate 1966). The number of jobs in the lumber and wood products sector peaked between 1972 and 1977 at 3,200 per year, or roughly 10 percent of the manufacturing jobs. By 1989, the number had declined to 2,500 , or 6 percent of the manufacturing workforce (University of New Mexico).
In 1986, New Mexico had 31 primary wood processing plants. They included 25 sawmills, two house log plants, and one each excelsior plant, fiberboard plant, pole and post treatment plant, and sawmill/post and pole yard. Nineteen of the plants are concentrated in north-central New Mexico (fig. 33).
All the timber harvested in 1986 was processed in the State. No out-ofState material was imported by New Mexico's mills.

## UNDERSTORY VEGETATION CONDITIONS

Habitat types and understory vegetation conditions provide more detail on forest land diversity in New Mexico. The inventory included ocular cover estimates of understory plant species with crown canopy cover of at least 5 percent of the plot area on each field location. For each of four life forms-trees, shrubs, forbs, and grasses-cover and heights were assessed.

Legend:
$S=$ Sawmills $H=$ House Logs $P P=$ Post and Poles $E=$ Excelsior $F B=$ Fiber Board
Source: McLain 1989a
Figure 33-Distribution of New Mexico's primary forest industry, 1987.

Much of New Mexico's forest land is, or has been, used for grazing. In fact, pinyon-juniper, oak, and mesquite woodlands are considered range types as well as forest types. The amount and types of understory vegetation on forest land sites can indicate general condition, as well as forage potential and availability. The understory observations were used to compile statistics of herbaceous and shrub cover by overstory canopy cover and owner group, for both timberland and woodland.
Understory vegetation data were sampled by Forest Survey crews on private and other public lands, and for the woodland inventory on the Lincoln National Forest. Although similar data are not available for other National Forest lands in New Mexico, average percent herbaceous cover by the major owner categories indicates a slight difference in condition:

Owner group

National Forest
Other public
Private

Average herbaceous cover Timberland Woodland
-- - - Percent ----

- 23

22
17
25 20

Percent tree cover, taken in classes, was cross-tabulated with average percent herbaceous cover. These data illustrate a pattern well documented in range literature: herbaceous understory cover decreases with increasing overstory cover:

Average herbaceous cover

## Overstory cover class

| $1(0-9 \%)$ | 42 | 42 |
| :--- | :--- | :--- |
| $2(10-24 \%)$ | 24 | 23 |
| $3(25-54 \%)$ | 25 | 16 |
| $4(55-84 \%)$ | 21 | 17 |
| $5(85-100 \%)$ | 17 | - |

Important Species Occurrence

Some interesting statistics about the occurrence of desirable or undesirable plants were obtained from the data. Broom snakeweed (Gutierrezia sarothrae) is an undesirable plant, cyclic in nature, that has increased rapidly on southwestern ranges in the last decade (McDaniel and others 1984). This shrub is poisonous to livestock and competes with desirable forage plants on disturbed sites. Broom snakeweed had at least 5 percent crown cover on 13 percent of all woodland, 2 percent of the National Forest woodland plots, 13 percent of the other public woodland plots, and 14 percent of the private woodland plots. Just 2 percent of the timberland plots had at least 5 percent canopy cover of broom snakeweed.

The most common plant species was blue grama (Bouteloua gracilis). Blue grama is a good forage species, but when grazed may increase into continuous mats that are not as desirable as a mix of species. This species was well represented (had at least 5 percent crown canopy cover) on 29 percent of all inventory locations and 37 percent of all woodland, 34 percent of other public woodland locations, 40 percent of the private woodland, and 27 percent of the National Forest woodland. Just 5 percent of the timberland was well represented with blue grama.

Two other species are useful for evaluating browse and winter range for big game-especially deer. Mountain-mahogany (Cercocarpus montanus) and antelope bitterbrush (Purshia tridentata) are highly desirable browse species. Mountain-mahogany was well represented on 4 percent of the timberland plots and 6 percent of the woodland plots. Antelope bitterbrush, limited to the northwestern part of the State, was well represented on only 1 percent of the plots.

Habitat Typing

Forest habitat type classification has proven useful to land managers in areas where such classifications have been developed. In the Southwest, habitat classification for woodlands is in its infancy. Habitat typing provides an ecological basis for categorizing environmental variations and improves prediction accuracy for characteristics such as potential timber and forage production. Climax vegetation serves as a key to the integrated environment, including climate, soil, and landform conditions. Timberland plots were habitat typed according to classification schemes by Alexander and others (1984), DeVelice and others (1986), Alexander and others (1987), and Fitzhugh and others (1987). In presenting the inventory data by habitat types, a different picture of the forest resources in New Mexico can be drawn based on a potential climax community. These habitat types have many silvicultural and other management prescriptions that can be obtained from the sources mentioned above. Table 83 includes a breakdown of the timberland plots by habitat type.
The most common habitat type was Pinus ponderosa/Quercus gambelii, occurring on 29 percent of other public and 30 percent of private timberland. According to Larson and Moir (1987), the resource value rating for cattle in this habitat type is moderate in early seral stages, and low to none in late seral stages. This type provides good wildlife hiding cover in summer and can provide good browse production from shrubs other than oak. Oak is an important source of mast for turkeys.
The second most common habitat type was Pseudotsuga menziesii/ Quercus gambelii, occurring on 13 percent of other public and 17 percent of private timberland. It has resource values similar to those for Pinus ponderosa / Quercus gambelii. Ponderosa pine plots are broken down by habitat type in figure 34.
The Pinus ponderosa/Muhlenbergia montana and P. ponderosa/Festuca arizonica habitat types are valuable for cattle grazing in early successional stages. These types occurred on 4 percent of other public and private land. Resource value ratings for additional habitat types can be obtained from the sources listed above.
Woodland plots were habitat typed by Forest Survey field crews only on the Lincoln National Forest, using the scheme of Larson and Moir (1986). Because these habitat types may be more descriptive of the present conditions than of a potential climax in woodlands, they will be referred to as community types for this report. The remainder of woodland plots were categorized into community types using the Forest Survey data base and guidelines established in the field guides by Larson and Moir $(1986,1987)$ and by Bassett and others (1987). Table 84 presents the number of Forest Survey woodland plots by community type.
One-third of the woodland plots were impossible to classify because of incomplete information. Of the plots classified, those with oak associations were the most common (36 percent). Pinus /Quercus or Juniperus/Quercus

Figure 34-Distribution of ponderosa pine series by habitat type, New Mexico, 1987.
community types have the potential to form closed canopies if they are not harvested or burned. These late seral stages would have low resource value ratings for cattle and for wildlife browse. The Pinus edulis / Cercocarpus montanus community type ( 2 percent of plots) is excellent habitat for wildlife browse and winter range. The Pinus edulis / Purshia tridentata community type ( 1 percent of plots) is important deer and elk winter range. Periodic fire may be necessary to maintain Purshia tridentata. The sparse community types ( 18 percent of plots) are probably derived from woodlands with a history of livestock grazing, and soil erosion, that have not burned. Other resource values are outlined in the field guides mentioned above. Ongoing research will provide more information for classification and interpretation of the woodland resource.

## SOIL SURFACE CONDITIONS

A certain amount of bare ground and associated erosion is an integral part of any arid ecosystem. Bare ground increases during drought. Past land-use history, including the removal of plants that hold the soil, has increased the problem of soil erosion. Observations of litter depth, percent bare ground, and degree of soil erosion were made at each field location to assess the general condition and stability of the State's forest soil resource.
About one-half of timberland plots and three-fourths of woodland plots show some evidence of soil erosion (fig. 35).

|  | Percent of field locations |  |
| :--- | :---: | :---: |
| Degree of erosion |  | 47 |
| None | 48 | 22 |
| Light (very little sheet <br> erosion evident) | 4 | 52 |
| Medium (both sheet and rill <br> erosion evident) | 1 | 20 |
| Heavy (bad rill erosion- <br> gullies evident) |  | 6 |

Some evidence of erosion was found on 63 percent of other public timberland plots, 52 percent of private timberland plots, 76 percent of National Forest woodland plots, 80 percent of other public woodland plots, and 78 percent of private woodland plots.
Seventy-three percent of woodland plots and 36 percent of timberland plots had more than 10 percent bare ground, with an average of 9 percent bare ground on timberland and 22 percent on woodland. The amount of bare ground is consistent across all owners in timberland, but on woodland plots, the average bare ground is 13 percent on National Forests, 25 percent on other public, and 22 percent on private land. Litter-undecomposed leaves, needles, twigs, bark, etc.-was absent from over half of the woodland field locations, but from only 3 percent of timberland locations.
Considerable amounts of bare ground, coupled with the low amounts of protective litter and sparse understory vegetation, indicate potential erosion problems on the forested lands of New Mexico, especially in the woodland. All of these soil erosion indicators substantiate the observations that widespread erosion exists.

Figure 35-Distribution of erosion by degree and type of plot, New Mexico, 1987.

## METHODS

On lands outside the National Forest System the Intermountain Research Station Forest Survey Program uses a two-phase or double sample for stratification for land classification and data collection. The first or map/photo phase consists of a grid of points established at a $1,000-\mathrm{m}$ interval on USGS quadrangle maps where map-based information such as county and congressional districts are assigned. The points are then transferred to aerial photography for interpretation into land cover classes. The second, or field phase consists of field visits to a subset of the first phase photo points. These are usually on a $5,000-\mathrm{m}$ grid.

Some 273,497 first phase points were established in New Mexico (fig. 36a). Of these, 9,747 were potential field plots, and 1,182 were actually forested (fig. 36b). All points determined to be timberland during the map/photo phase were subsampled using the $5,000-\mathrm{m}$ selection rule. Those determined to be woodland were subsampled at the $5,000-\mathrm{m}$ intensity in all units of the State except the northeast. Here a double $10,000-\mathrm{m}$ grid was used, resulting in a spacing of about $7,100 \mathrm{~m}$. The final sample included 322 timberland plots, 860 woodland plots, and 8,565 nonforest plots.

Each timberland field plot consisted of up to five satellite points dispersed systematically over an acre of timberland. At each point, trees 5.0 inches d.b.h. and larger were selected for measurement on a variable radius plot defined by a 20 -basal-area-factor (BAF) prism on ponderosa pine locations and a $40-\mathrm{BAF}$ prism for other timberland locations. Trees from 1.0 to 4.9 inches d.b.h. were tallied on a $1 / 300$-acre fixed-radius subplot. Seedlings were tallied only if no trees greater than 1.0 inch d.b.h. were recorded on a point.

Each woodland plot consisted of a $1 / 20$-acre, a $1 / 10$-acre, or a $1 / 5$-acre fixed radius plot. All trees 3.0 inches d.r.c. and larger were tallied on this plot. Trees 1.0 to 2.9 inches d.r.c. were tallied on up to four $1 / 300-$ acre subplots, and seedlings were tallied only if no trees greater than 1.0 inch d.r.c. were tallied on a subplot.

The tree measurements were used to estimate volume, basal area, number of trees, and other per-acre variables, by applying volume equations developed by Chojnacky (1985), Hann and Bare (1978), and Edminster (1977), and other algorithms developed by the Forest Survey Program. Expansion factors, developed by adjusting the map/photo point information to meet known land areas, were applied to these per-acre estimates to generate population totals. This information was combined with similar information from the Forest Service's Southwest Region Timber Management staff to develop the resource summaries presented in this report.

In addition to the detailed tree measurements, several plot-level variables were recorded on both timberland and woodland field locations. These included indicators of use by humans, wildlife, and domestic animals; indicators of understory vegetative structure and condition; size of the forest condition and its juxtaposition to nonforest areas; and other timber and nontimber items. A more complete discussion of this procedure can be found in Van Hooser and others (1990).

## SAMPLING ERROR

The sampling methods were designed to achieve suitable sampling errors for estimates of area and volume at the State level. Sampling error increases

Figure 36-Distribution of Phase I map/photo points and Phase II field sample points, New Mexico,
1987. A. Phase I, 1,000-meter points.

Figure 36-(Con.) B. Phase II, 5,000-meter field points.
as the area or volume considered decreases. The sampling errors presented in tables 2 and 3, equal to one standard deviation for the sample data, may be used to compute confidence intervals for population estimates. For example, at the 95 percent confidence level, the confidence interval for total growing-stock volume (in million cubic feet) is:

$$
5,992.4 \pm 1.96(0.031 \times 5,992.4)=5,992.4 \pm 364.1
$$

where 1.96 is the number of standard deviations. This confidence interval indicates a 0.95 probability that the range $5,628.3$ to $6,356.5$ million cubic feet will cover the true growing-stock inventory volume.

The results are reported for individual items and individual counties so that users may combine them as desired. It is not recommended that individual item or county data be used in isolation. The user should aggregate data cells as much as possible. Sampling error for a combination of data items or counties may be estimated using the following formula:

$$
S E_{g}=\frac{S E_{t} \sqrt{X_{t}}}{\sqrt{X_{g}}}
$$

where

$$
\begin{aligned}
S E= & \text { standard error of the estimate } \\
& \text { (expressed as a percent) } \\
X & =\text { variable of interest (area or volume) } \\
g & =\text { group of counties to be combined } \\
t & =\text { total for the State }
\end{aligned}
$$

For example, the estimate of sampling error for growing-stock volume on timberland in Rio Arriba, Sandoval, and Taos Counties is 4.8 percent. The 95 percent confidence interval of growing-stock volume is $2,460.1 \pm 231.4$ million cubic feet.

## TERMINOLOGY

Acceptable trees-Growing-stock trees meeting specified standards of size and quality but not qualifying as desirable trees.

Area condition class-A classification of timberland reflecting the degree to which the site is being utilized by growing-stock trees and other conditions affecting current and prospective timber growth (see Stocking):
Class 10-Areas fully stocked with desirable trees and not overstocked.
Class 20-Areas fully stocked with desirable trees but overstocked with all live trees.
Class 30-Areas medium to fully stocked with desirable trees and with less than 30 percent of the area controlled by other trees, or inhibiting vegetation or surface conditions that will prevent occupancy by desirable trees, or both.
Class 40-Areas medium to fully stocked with desirable trees and with 30 percent or more of the area controlled by other trees, or conditions that ordinarily prevent occupancy by desirable trees, or both.
Class 50-Areas poorly stocked with desirable trees but fully stocked with growing-stock trees.
Class 60-Areas poorly stocked with desirable trees, but with medium to full stocking of growing-stock trees.
Class 70-Areas nonstocked or poorly stocked with desirable trees and poorly stocked with growing-stock trees.

Class 80-Low-risk mature stands.
Class 90-High-risk mature stands.
Nonstocked-Areas less than 10 percent stocked with growing-stock trees.

Basal area-The cross-sectional area of a tree expressed in square feet. For timber species the calculation is based on diameter at breast height (d.b.h.); for woodland species it is based on diameter at root collar (d.r.c.).

Christmas tree grade-Pinyon species are classified as Christmas trees using the following guidelines:

Premium-Excellent conical form with no gaps in branches and a straight bole.
Standard-Good conical form with small gaps in branches and bole slightly malformed.
Utility-Conical in form with branches missing and bole bent or malformed.
Cull-Not meeting one of the above classifications or over 12 feet in height.
Cord-A pile of stacked wood equivalent to 128 cubic feet of wood and air space having standard dimensions of 4 by 4 by 8 feet.
Cull trees-Live trees that are unmerchantable now or prospectively (see Rough trees and Rotten trees).
Cull volume-Portions of a tree's cubic-foot volume that are not usable for wood products because of rot, missing and/or dead material, or other defect.

Desirable trees-Growing-stock trees (1) having no serious defect in quality to limit present or prospective use for timber products, (2) showing relatively high vigor, and (3) containing no pathogens that may result in death or serious deterioration within the next decade.
Diameter at breast height (d.b.h.) -Diameter of the stem measured 4.5 feet above the ground.

Diameter at root collar (d.r.c.)-Diameter equivalent at the point nearest the ground line that represents the basal area of the tree stem or stems.

Diameter classes-Tree diameters, either d.b.h. or d.r.c., grouped into 2 -inch classes labeled by the midpoint of the class.

Farmer/rancher-owned lands-Lands owned by a person who operates a farm or a ranch and who either does the work or directly supervises the work.
Fenceposts-Juniper and oak species are evaluated for post potential using the following criteria:

Line post-A 7 -foot minimum length with 5 to 7 inches diameter at the butt, 2.5 inch minimum small end diameter, and reasonably straight and solid.
Corner post-An 8-foot minimum length with 7 to 9 inches diameter at the butt, 2.5 inch minimum small end diameter, and reasonably straight and solid.
Forest industry lands-Lands owned by companies or individuals operating a primary wood-processing plant.

Forest lands-Lands at least 10 percent stocked by forest trees of any size, including lands that formerly had such tree cover and that will be naturally or artificially regenerated. The minimum area for classification of forest land is 1 acre. Roadside, streamside, and shelterbelt strips of timber must have a crown width at least 120 feet wide to qualify as forest land. Unimproved roads and trails, streams, and clearings in forest areas are classified as forest if less than 120 feet wide.

Forest trees-Woody plants having a well-developed stem or stems, usually more than 12 feet in height at maturity, with a generally well-defined crown.

Forest type-A classification of forest land based upon and named for the tree species forming a plurality of live-tree stocking.
Gross annual growth-The average annual increase in the net volume of trees.

Growing-stock trees-Live sawtimber trees, poletimber trees, saplings, and seedlings of timber species meeting specified standards of quality and vigor; excludes cull trees.

Growing-stock volume-Net cubic-foot volume in live poletimber-size and sawtimber-size growing-stock trees from a 1 -foot stump to a minimum 4 -inch top (of central stem) outside bark, or to the point where the central stem breaks into limbs.

Growth-See definition for Net annual growth.
Hardwood trees-Trees that are usually broad-leaved and deciduous.
High-risk mature stands-Timber stands over 100 years old in which the majority of the trees are not expected to survive more than 10 years.
Indian trust lands-Indian lands held in trust by the Federal Government.
Industrial wood-All commercial roundwood products except fuelwood.
Land area-The area of dry land and land temporarily or partially covered by water such as marshes, swamps, and river flood plains, streams, sloughs, estuaries, and canals less than 120 feet wide; and lakes, reservoirs, and ponds less than 1 acre in size.

Logging residues-The unused portions of growing-stock trees cut or killed by logging.

Low-risk mature stands-Timber stands over 100 years old in which the majority of the trees are expected to survive more than 10 years.

Mature stands-Stands of timber species over 100 years old.
Miscellaneous Federal lands-Lands administered by Federal agencies other than the U.S. Department of Agriculture, Forest Service, or U.S. Department of the Interior, Bureau of Land Management.

Mortality-The net volume of growing-stock trees that have died from natural causes during a specified period.
National Forest lands—Public lands administered by the U.S. Department of Agriculture, Forest Service.

National Resource lands-Public lands administered by the U.S. Department of the Interior, Bureau of Land Management.
Net annual growth-Gross annual growth minus average annual mortality.
Net dead volume-Total net volume of dead trees plus the net volume of dead material in live trees.

Net volume in board feet-The gross board-foot volume in the sawlog portion of growing-stock trees, less deductions for cull volume.
Net volume in cubic feet-Gross cubic-foot volume in the merchantable portion of trees, less deductions for cull volume. For timber species, volume is computed for the merchantable stem from a 1 -foot stump to a minimum 4-inch top diameter outside bark (d.o.b.), or to the point where the central stem breaks into limbs. For woodland species, volume is computed outside bark for all woody material above the root collar that is larger than 1.5 inches d.o.b.
Nonforest lands-Lands that do not currently qualify as forest land.
Nonindustrial private-All private ownerships except forest industry.
Nonstocked areas-Forest land less than 10 percent stocked with live trees.
Other private lands-Privately owned lands other than those owned by forest industry or farmer/rancher.
Other public lands-Public lands administered by agencies other than the U.S. Department of Agriculture, Forest Service.

Other removals-The net volume of growing-stock trees removed from the inventory by silvicultural operations such as timber-stand improvement, by land clearing, and by changes in land use, such as a shift to wilderness.
Poletimber stands-Stands at least 10 percent stocked with growing-stock trees, in which half or more of the stocking is sawtimber or poletimber trees or both, with poletimber stocking exceeding that of sawtimber (see definition for Stocking).
Poletimber trees-Live trees of timber species at least 5 inches d.b.h. but smaller than sawtimber size.

Potential growth-The average net annual cubic-foot growth per acre at culmination of mean annual growth attainable in fully stocked natural stands.

Primary wood-processing plants-Plants using roundwood products such as sawlogs, pulpwood bolts, veneer logs, and so forth.
Productivity class-A classification of forest land that reflects biological potential. For timberland, the index used is the potential net annual growth at culmination of mean annual increment in fully stocked natural stands. For woodland, characteristics that are used affect the land's ability to produce wood, such as soil depth and aspect. Furthermore, woodland is classified as high site where sustained wood production is likely, or low site where the continuous production of wood is unlikely.

Removals-The net volume of growing-stock trees removed from the inventory by harvesting, silivicultural operations, land clearings, or changes in land use.
Reserved forest land-Forest land withdrawn from tree utilization through statute or administrative designation.

## Residues:

Coarse residues-Plant residues suitable for chipping, such as slabs, edgings, and ends.
Fine residues-Plant residues not suitable for chipping, such as sawdust, shavings, and veneer clippings.
Plant residues-Wood materials from primary manufacturing plants not used for any product.
Rotten trees-Live poletimber or sawtimber trees with more than 67 percent of their total volume cull (cubic-foot) and with more than half of the cull volume attributable to rotten or missing material.
Rough trees-Live poletimber or sawtimber trees with more than 67 percent of their total volume cull (cubic-foot) and with less than half of the cull volume attributable to rotten or missing material.
Roundwood-Logs, bolts, or other round sections cut from trees.
Salvable dead trees-Standing or down dead trees that are currently merchantable by regional standards.

Saplings-Live trees of timber species 1 to 4.9 inches d.b.h., or woodland species 1 to 2.9 inches d.r.c.
Sapling and seedling stands-Timberland stands at least 10 percent stocked on which more than half of the stocking is saplings or seedlings or both.
Sawlog portion-That part of the bole of sawtimber trees between a 1 -foot stump and the sawlog top.
Sawlog top-The point on the bole of sawtimber trees above which a sawlog cannot be produced. The minimum sawlog top is 7 inches d.o.b. for softwoods and 9 inches d.o.b. for hardwoods.
Sawtimber stands-Stands at least 10 percent stocked with growing-stock trees, with half or more of total stocking in sawtimber or poletimber trees, and with sawtimber stocking at least equal to poletimber stocking.
Sawtimber trees-Live trees of timber species meeting regional size and defect specifications. Softwood trees must be at least 9 inches d.b.h. and hardwood trees 11 inches d.b.h.
Sawtimber volume-Net volume in board feet of the sawlog portion of live sawtimber trees.
Seedlings-Established live trees of timber species less than 1 inch d.b.h., or woodland species less than 1 inch d.r.c.
Softwood trees-Coniferous trees that are usually evergreen and have needles or scalelike leaves.

Standard error-An expression of the degree of confidence that can be placed on an estimated total or average obtained by statistical sampling methods. Standard errors do not include technique errors that could occur in photo classification of areas, field measurements, or compilation of data.

Stand-size classes-A classification of forest land based on the predominant size of trees present (see Sawtimber stands, Poletimber stands, and Sapling and seedling stands).

State, county, and municipal lands-Lands administered by States, counties, and local public agencies, or lands leased by these governmental units for more than 50 years.

Stocking-An expression of the extent to which growing space is effectively used by present or potential growing-stock trees of timber species.
Timberland-Forest land where timber species make up at least 10 percent stocking. (FSH 4809.11 defines commercial forest land as land producing, or capable of producing, crops of industrial wood and not withdrawn from timber utilization. This is synonymous with the Timberland definition above.)
Timber species-Tree species traditionally used for industrial wood products. In the Rocky Mountain States, these include aspen and cottonwood hardwood species and all softwood species except pinyon and juniper.
Timber stand improvement-Treatments such as thinning, pruning, release cutting, girdling, weeding, or poisoning unwanted trees to improve growing conditions for the remaining trees.

Upper-stem portion-That part of the main stem or fork of sawtimber trees above the sawlog top to a minimum top diameter of 4 inches outside bark or to the point where the main stem or fork breaks into limbs.
Water-Streams, sloughs, estuaries, and canals more than 120 feet wide, and lakes, reservoirs, and ponds more than 1 acre in size at mean high water level.

Wilderness-An area of undeveloped land in the Wilderness System, managed so as to preserve its natural conditions and retain its primeval character.

Woodland-Forest land where timber species make up less than 10 percent stocking.

Woodland species-Tree species not usually converted into industrial wood products. Common uses are fuelwood, fenceposts, and Christmas trees.

${ }^{1}$ Because many destructive agents often attack trees in concert or in succession, it is often difficult to identify the actual causal agent. When the primary cause of death cannot be precisely determined, it is listed as unknown.

Van Hooser, Dwane D.; O'Brien, Renee A.; Collins, Dennis C. 1993. New Mexico's forest resources. Resour. Bull. INT-79. Ogden, UT: U.S. Department of Agriculture, Forest Service, Intermountain Research Station. 110 p.

Presents land area, timberland and woodland area, associated volume, and components of change for the forest lands in New Mexico.

KEYWORDS: forest surveys, inventories, volume, growth, mortality, removals, forest inventories

The Intermountain Research Station provides scientific knowledge and technology to improve management, protection, and use of the forests and rangelands of the Intermountain West. Research is designed to meet the needs of National Forest managers, Federal and State agencies, industry, academic institutions, public and private organizations, and individuals. Results of research are made available through publications, symposia, workshops, training sessions, and personal contacts.

The Intermountain Research Station territory includes Montana, Idaho, Utah, Nevada, and western Wyoming. Eighty-five percent of the lands in the Station area, about 231 million acres, are classified as forest or rangeland. They include grasslands, deserts, shrublands, alpine areas, and forests. They provide fiber for forest industries, minerals and fossil fuels for energy and industrial development, water for domestic and industrial consumption, forage for livestock and wildlife, and recreation opportunities for millions of visitors.

Several Station units conduct research in additional western States, or have missions that are national or international in scope.

Station laboratories are located in:
Boise, Idaho
Bozeman, Montana (in cooperation with Montana State University)
Logan, Utah (in cooperation with Utah State University)
Missoula, Montana (in cooperation with the University of Montana)
Moscow, Idaho (in cooperation with the University of Idaho)
Ogden, Utah
Provo, Utah (in cooperation with Brigham Young University)
Reno, Nevada (in cooperation with the University of Nevada)
USDA policy prohibits discrimination because of race, color, national origin, sex, age, religion, or handicapping condition. Any person who believes he or she has been discriminated against in any USDA-related activity should immediately contact the Secretary of Agriculture, Washington, DC 20250.

[^0]:    1These lands are reserved and are included in tables 1, 2, and 4 only.
    ${ }^{2}$ U.S. Department of Commerce, Bureau of Census, 1980.

[^1]:    ${ }^{1}$ Reserved land areas are estimated from aerial photos with field verification; therefore, standard errors are not calculated.
    ${ }^{2}$ On this and all following tables, totals may vary due to rounding.

[^2]:    ${ }^{1}$ International $1 / 4$-inch rule.
    ${ }^{2}$ Scribner rule.

[^3]:    ${ }^{1}$ Less than 500 cubic feet.

[^4]:    ${ }^{1}$ Hardwoods are not considered sawtimber until they are 11 inches d.b.h.

[^5]:    'Less than 500 cubic feet.

[^6]:    ${ }^{1}$ Less than 500 cubic feet.
